Apneic Seizures: A Sign of Temporal Lobe Hemorrhage in Full-Term Neonates

Deepa Sirsi, MD, Lakshmi Nadiminti, MD, Maurine A. Packard, MD, Murray Engel, MD, and Gail E. Solomon, MD

Intracranial hemorrhage is a common cause of neonatal seizures in full-term infants. However, only some infants with intracranial hemorrhage come to clinical attention. A right temporal lobe hemorrhage with resulting apneic seizures was described previously in one neonate. In this case report, we review three full-term male neonates with no significant perinatal complications who presented with apneic events and temporal lobe hemorrhage. One neonate had apnea as the sole manifestation of a seizure that was confirmed electrographically. One neonate had motor manifestations of seizures, in addition to apnea, that were confirmed as seizures electrographically. The third neonate had pure apneic events before initiation of electroencephalogram monitoring which were presumed to be seizures, because the electroencephalogram demonstrated epileptiform abnormalities. At follow-up, all three children were neurodevelopmentally normal. This case report emphasizes that, although uncommon, full-term neonates may present with apnea as the initial manifestation of a seizure. The association of temporal lobe intracranial hemorrhage and apneic seizures in full-term neonates was reported previously [3]. The previous literature and our three case presentations demonstrate the need for an index of suspicion for seizures as the etiology of apnea, and a need to initiate continuous electroencephalogram monitoring in neonates with unexplained apnea.

Case Report

We describe three neonates who presented with apnea as the initial manifestation of underlying temporal lobe hemorrhage. The pregnancy and perinatal histories of the three neonates are summarized in Table 1.

All three neonates had sepsis evaluations at presentation, and were started on antibiotics pending cultures. Initial laboratory test results, including hematocrit, platelets, and chemistries (electrolytes, glucose, calcium), were normal.

An electroencephalogram was performed using digital equipment from XLTEK (Oakville, Ontario, Canada), with a standard neonatal montage in all patients. The main clinical, electrographic, and imaging findings, hematology investigations, cardiology evaluations, and clinical follow-up information from the three neonates are summarized in Table 2.

Patient 1

With his first feed 3 hours after birth, this male neonate was noted to be dusky, and was transferred to our Neonatal Intensive Care Unit. Subsequently, he had recurrent periods of apnea for 20-50 seconds, with oxygen desaturations to 50 percent during periods of apnea. One episode was associated with conjugate eye deviation to the right, and right-arm clonic jerking, lasting 30 seconds. No changes in heart rate were observed during these events.
An examination showed a head circumference of 33.5 cm (10th percentile for age). His vital signs were normal. No cephalhematoma was noted. He had a gaze preference to the left (likely a postictal state) that resolved over the next 24 hours. A neurologic examination produced normal results otherwise. Lumbar puncture results were significant for 53,000 red blood cells.

Electroencephalogram monitoring demonstrated multiple electrographic seizures of left hemispheric origin that were clinically accompanied by apnea and oxygen desaturation. The onset of apnea was 5 seconds after the onset of electrographic seizure. The patient was intubated for recurrent apnea, and was concurrently loaded with phenobarbital. Apneic events and electrographic seizure activity resolved after a phenobarbital level of 34 μg/mL was attained.

A head ultrasound demonstrated an echogenic focus in the left temporoparietal area. Magnetic resonance imaging indicated a left temporal and parietal intraparenchymal hemorrhage, with adjacent subdural hematomas. Magnetic Resonance Angiogram and Magnetic Resonance Venogram produced normal results.

Figure 1 depicts a characteristic electrographic seizure emanating predominantly from the left temporal lobe which was accompanied clinically by apnea and oxygen desaturation. Seizure was characterized at onset by sharply contoured, rhythmic delta activity for 3-5 seconds. This activity evolved into faster-frequency alpha with admixed theta sharp-and-slow-wave activity, most prominent in the left temporal region. This activity lasted 25 seconds, and was followed by diffuse attenuation and slowing. Figure 2 is an axial, gradient echo sequence demonstrating a left temporal lobe hemorrhage with an adjacent subdural hematoma.

Subsequent magnetic resonance imaging of the brain at age 10 days revealed restricted diffusion of the left temporal cortex suggesting infarction, the expected evolution of subdural hematomas, and a resolution of the minimal mass effect.

An electroencephalogram at age 12 days indicated frequent left temporal spikes at T3 and T5, with phase reversal at T3 accompanied by no behavioral change. No seizures were noted. Continuous left hemispheric attenuation occurred.

**Patient 2**

At 2 hours of age, this newborn male had apneic episodes with oxygen desaturations to 40 percent. There was no relationship of these episodes to feedings. No change in heart rate was observed during the episodes. No movements suggesting seizures were noted. During these events, he responded to vigorous stimulation and blow-by oxygen.

His examination showed a head circumference of 36 cm (90th percentile for age). His vital signs were normal. There was no cephalhematoma or skull fracture. No neurologic deficits were found. A head ultrasound obtained at age 2 days indicated echogenicity in the posterior right temporal lobe. Magnetic resonance imaging revealed a right temporal intraparenchymal hemorrhage, and Magnetic Resonance Venogram demonstrated a right sigmoid sinus thrombosis. Hypercoagu-

Discussion

Apnea as sole manifestation of a seizure in a full-term neonate is rare [3]. One report described four term neonates with apnea and additional motor movements correlating with electrographic seizures [4]. Watanabe et al. [2] described 19 term neonates with apnea and electrographic seizures, of whom only three were purely apneic, and 11 had an associated, subtle clinical phenomenon. One of the four term neonates with apnea and

Apnea occurring beyond the neonatal period is very rare, and has received attention as a possible precursor to apparent life-threatening events [7]. Previous reports found that intracranial hemorrhages in the majority of infants with apneic seizures are in areas other than the temporal lobes [6]. Although the neonates we describe had hemorrhages predominantly in the temporal lobes, this may be because of the small number of patients in our study.

Epileptic apnea is thought to originate from the limbic system [2,7]. Electroencephalograms in older infants and children with apneic seizures usually indicate focal repetitive spike and wave discharges, most often originating in the temporal lobes without a corresponding structural lesion [6,7]. In contrast, the ictal electroencephalograms of apneic seizures of most previously reported newborns demonstrate bilateral rhythm.

mic monomorphic activity in the theta and alpha bands, originating in the central areas [8].

Our patients were unusual, in that 2 of 3 neonates had temporal lobe ictal and interictal epileptiform activity, similar to the electroencephalogram findings in older infants with apneic seizures, and differing from most reported neonates with apneic seizures who have more generalized abnormalities. In addition, unlike older infants, our patients had structural abnormalities corresponding to the ictal focus described in one previous neonate [3].

The background activity of the electroencephalogram was normal for age, which correlated with their good short-term developmental outcome. However, further follow-up is necessary to determine a long-term prognosis.

Intraparenchymal hemorrhage in the term infant is relatively uncommon [9]. Most neonates with isolated intraparenchymal hemorrhages are of normal birth weight, without prenatal complications, and with uncomplicated deliveries [10]. No specific cause for the bleeding is identified in many of these children [9,11]. Undetected hypoxic-ischemic injury was hypothesized to be a cause of intracranial hemorrhage in the term neonate. However, the high Apgar scores and eventual good outcome argue against this possibility [10].

Although all three neonates also had other compartments involved, the most significant abnormality in each was in the temporal lobe. This finding likely explains the favorable outcome.

Potential explanations for intraparenchymal hemorrhages include arterial and venous occlusion with hemorrhagic infarction. This occlusion may be secondary to emboli arising spontaneously from thrombosis in involuting umbilical veins, arteries, or the ductus arteriosus. Local trauma with resultant venous or capillary injury, and cortical trauma from parturition, are also implicated [9-12].

The sites of intraparenchymal hemorrhage in these reports were most commonly temporal. An unprotected sutural confluence adjacent to the pterion is postulated as the site of hemorrhage.
a potential location for vascular injury because of molding during delivery [13]. As in our three patients, surgical evacuation has not played a role in the management of the majority of infants described in the literature [12].

Conclusions

It is important to recognize that, although uncommon, full-term neonates may present with apnea as the initial manifestation of either right or left temporal lobe intracranial hemorrhage. Determination of the cause of apnea is important for proper treatment, because therapy differs according to diagnosis. A high index of suspicion should be maintained for seizures as the etiology of apnea. Continuous electroencephalogram monitoring is valuable in correlating apnea to electrographic activity, and should be considered in term neonates with unexplained apnea. Early detection of seizures can lead to investigation into the etiology and appropriate management of the intracranial hemorrhage and facilitate prompt management of seizures, which may help reduce the degree of neurodevelopmental disability.
